A New Algorithm with Low Complexity for Adaptive Filtering

M. Arezki, A. Benallal, P. Meyrueis and D. Berkani

Abstract—In this paper, we propose a new algorithm M-SMFTF for adaptive filtering with fast convergence and low complexity. It is the result of a simplified FTF type algorithm, where the adaptation gain is obtained only from the forward prediction variables and using a new recursive method to compute the likelihood variable. The computational complexity was reduced from $7L$ to $6L$, where $L$ is the finite impulse response filter length. Furthermore, this computational complexity can be significantly reduced to $(2L+4P)$ when used with a reduced $P$-size forward predictor. This algorithm presents a certain interest, for the adaptation of very long response filter length. Furthermore, this computational complexity which is slightly greater than the one of the normalized LMS algorithm.

Index Terms— Fast RLS, NLMS, FNTF, Adaptive Filtering, Convergence Speed, Tracking capability.

I. INTRODUCTION

There are two major classes of adaptive algorithms [1]-[3]. One is the least mean square (LMS) algorithm, which is based on a stochastic gradient method. The LMS algorithm has a computational complexity of $O(L)$, $L$ is the finite impulse (FIR) filter length. The other class of adaptive algorithm is the recursive least-squares (RLS) algorithm which minimizes a deterministic sum of squared errors [4]. The RLS algorithm solves this problem, but at the expense of increased computational complexity of $O(L^3)$. A large number of fast RLS (FRLS) algorithms have been developed over the years, but, unfortunately, it seems that the better a

FRLS algorithm is in terms of computational efficiency, the more severe is its problems related to numerical stability [4]. Fast versions of these algorithms, namely, the fast Kalman [5], the fast a posteriori error sequential technique (FAEST) [6], and fast transversal filter (FTF) [7] algorithms, are derived from the RLS by the introduction of forward and backward predictors. The FRLS algorithm shows a complexity of $O(L)$. Several numerical solutions of stabilization, with stationary signals, are proposed in the literature [8]-[12]. Another way of reducing the complexity of the fast RLS (FRLS) algorithm has been proposed in [13], [14]: When the input signal can be accurately modelled by a predictor of order $P$, the fast Newton transversal filter (FNTF) avoids running forward and backward predictors of order $L$, which would be required by a FRLS algorithm. The required quantities are extrapolated from the predictors of order $P$ ($P<<L$). Thus, the complexity of the FNTF falls down to $(2L+12P)$ multiplications instead of $8L$. Recently, the simplified FTF-type algorithm [15] developed for use in acoustic echo cancellers. This algorithm derived from the FTF algorithm where the adaptation gain is obtained only from the forward prediction variables. The computational complexity of this algorithm is $7L$ when used with a full size predictor which is less complex than the original numerically stable $8L$ FTF algorithm.

In this paper, we propose more complexity reduction of the simplified FTF-type algorithm by using a new recursive method to compute the likelihood variable. The computational complexity of the proposed algorithm is $6L$ and this computational complexity can be significantly reduced to $(2L+4P)$ when used with a reduced $P$-size forward predictor. The M-SMFTF of the proposed algorithm outperforms the classical adaptive algorithms because of its convergence speed which approaches that of the RLS algorithm and its computational complexity which is slightly greater than the one of the NLMS algorithm. We describe the NLMS and numerically stable FRLS (NS-FRLS) algorithms. More complexity reduction for simplified FTF-type (M-SMFTF) algorithm is proposed. At the end, we present some simulation results of the M-SMFTF algorithm.

II. ADAPTIVE ALGORITHMS

The main identification block diagram of a linear system with finite impulse response (FIR) is represented in Fig.1. The output a priori error $\hat{e}_{L,n}$ of this system at time $n$ is:

$$\hat{e}_{L,n} = d_n - \hat{y}_n$$

(1)
where \( \hat{y}_n = w_{L,n}^T x_{L,n} \) is the model filter output, \( x_{L,n} = [x_n, \ldots, x_{n-L+1}]^T \) is a vector containing the last \( L \) samples of the input signal \( x_n \), \( w_{L,n} = [w_{L,n-1}, \ldots, w_{L,n-1}] \) is the coefficient vector of the adaptive filter and \( L \) is the filter length. The desired signal from the model is:

\[
d_n = v_n + w_{\text{opt},L}^T x_{L,n}
\]

where \( w_{\text{opt},L} = [w_{\text{opt},1}, \ldots, w_{\text{opt},L}] \) represents the unknown system impulse response vector and \( v_n \) is a stationary, zero-mean, and independent noise sequence that is uncorrelated with any other signal. The superscript \( t \) describes transposition. The filter is updated at each instant by feedback of the estimation error proportional to the adaptation gain, denoted as \( \gamma \), and according to:

\[
w_{L,n} = w_{L,n-1} + g_{L,n} \bar{e}_{L,n}
\]

The different algorithms are distinguished by the gain calculation.

### A. The NLMS Algorithm

Algorithms derived from the gradient [3], for which the optimization criterion corresponds to a minimization of the mean-square error. For the normalized LMS (NLMS) algorithm, the adaptation gain is given by:

\[
g_{L,n} = \frac{\mu}{L \pi_{x,n} + c_0}
\]

where \( \mu \) is referred to as the adaptation step and \( c_0 \) is a small positive constant used to avoid division by zero in absence of the input signal. The stability condition of this algorithm is \( 0 < \mu < 2 \) and the fastest convergence is obtained for \( \mu = 1 \) [16]. The power \( \pi_{x,n} \) of input signal can alternatively be estimated using the following recursive equation [17]:

\[
\pi_{x,n} = (1 - \gamma) \pi_{x,n-1} + \gamma \xi_n^2
\]

where \( \gamma \) is a forgetting factor (\( \gamma \approx 1/L \)). The computational complexity of the NLMS algorithm is \( 2L \) multiplications per sample.

### B. The NS-FRLS Algorithm

The filter \( w_{L,n} \) is calculated by minimizing the weighted least squares criterion according to [1]:

\[
J_\lambda (w) = \sum_{i=1}^{n} \lambda^{n-i} (d_i - w_{L,n}^T x_{L,i})^2
\]

where \( \lambda \) denotes the exponential forgetting factor (\( 0 < \lambda \leq 1 \)). The adaptation gain is given by:

\[
g_{L,n} = \frac{\lambda \bar{R}_{L,n} \bar{y}_{L,n} - \gamma_{L,n}}{\lambda \bar{R}_{L,n} + \gamma_{L,n}}
\]

\[
\bar{R}_{L,n} = \sum_{i=1}^{n} \lambda^{n-i} x_{L,i} x_{L,i}^T = \lambda \bar{R}_{L,n-1} + x_{L,n} x_{L,n}^T
\]

where \( \bar{R}_{L,n} \) is an estimate of the correlation matrix of the input signal vector. The variables \( \gamma_{L,n} \) and \( \tilde{k}_{L,n} \) respectively indicate the likelihood variable and normalized Kalman gain vector. This latter is calculated, independently of the filtering part \( w_{L,n} \), by a fast RLS (FRLS) algorithm using forward/backward linear prediction analysis over the signal \( x_n \) [1]. The calculation complexity of a FRLS algorithm is of order \( L \). This reduction of complexity, compared to that of RLS algorithms, which have a complexity of order \( L^2 \), have made all FRLS algorithms numerically unstable.

The numerical stability is achieved by using a control variable, also called a divergence indicator \( \xi_n \) [11], theoretically equals to zero. Its introduction in an unspecified point of the algorithm modifies its numerical properties. It is obtained by using some redundant formulae of the FRLS algorithms. This variable is given by

\[
\xi_n = \bar{r}_{L,n} - \bar{r}_{L,n}^{(0)} = 0 \quad \text{theory}
\]

\[
\xi_n 
eq 0 \quad \text{practical}
\]

with \( \bar{r}_{L,n} = [1 - \mu_1] \bar{r}_{L,n}^{(1)} + \mu_1 \bar{r}_{L,n}^{(0)} \) and \( 0 \leq \mu_1 \leq 1 \), where \( \bar{r}_{L,n}^{(1)}, \bar{r}_{L,n}^{(0)} \) and \( \bar{r}_{L,n}^{(0)} \) are the backward a priori prediction errors calculated in tree differently ways. We define three backward a priori prediction errors, theoretically equivalents, which will be used to calculate the likelihood variable \( \gamma_{L,n} \), the backward prediction error variance \( \beta_{L,n} \) and the backward prediction \( b_{L,n} \) . We introduce these variables into the algorithm, and we use suitably the scalar parameters \( (\mu^\alpha , \mu^\beta , \mu^\gamma) \) and \( \mu_x \), in order to obtain the numerical stability. It can be shown that the variance of the numerical errors in the backward predictor, with the assumption of a white Gaussian input signal, is stable under the following condition [11]:

\[
\lambda > 1 - 1/2L
\]

The resulting stabilized FRLS (NS-FRLS) algorithms have a complexity of \( 8L \) as shown in Table I. Note that

![Diagram of an adaptive filter](Fig.1: Main block diagram of an adaptive filter)
numerical stabilization of the algorithm limits the range of the forgetting factor $\lambda$ (10) and consequently their convergence speed and tracking ability.

III. PROPOSED ALGORITHMS

A. The M-SMFTF Algorithm

We propose more complexity reduction of the simplified FTF-type (M-SMFTF) algorithm by using a new recursive method to compute the likelihood variable. The Simplified FTF-type algorithm [15] derived from the FTF algorithm where the adaptation gain is obtained only from the forward prediction variables. The backward prediction variables, which are the main source of the numerical instability in the FRLS algorithms, are completely discarded. By using only forward prediction variables and adding a small regularization constant $c_a$ and a leakage factor $\eta$, we obtain a robust numerically stable adaptive algorithm that shows the same performances as FRLS algorithms.

If we discard all backward prediction variables and use only the forward variables from the equation:

$$
\begin{bmatrix}
\tilde{k}_{L,a} \\
0
\end{bmatrix} = \frac{-1}{\lambda \alpha_{L,a-1}} \begin{bmatrix}
\tilde{e}_{L,a} \\
\tilde{k}_{L,a-1}
\end{bmatrix} + \begin{bmatrix}
1 \\
-a_{L,a-1}
\end{bmatrix} \begin{bmatrix}
\tilde{e}_{L,a} \\
\tilde{k}_{L,a-1}
\end{bmatrix}
$$

(11)

the normalized Kalman gain can be rewritten as follows:

$$
\begin{bmatrix}
k_{L,a} \\
*\end{bmatrix} = \frac{-1}{\lambda \alpha_{L,a-1}} \begin{bmatrix}
\tilde{e}_{L,a} \\
\tilde{k}_{L,a-1}
\end{bmatrix} + \begin{bmatrix}
1 \\
-a_{L,a-1}
\end{bmatrix} \begin{bmatrix}
\tilde{e}_{L,a} \\
\tilde{k}_{L,a-1}
\end{bmatrix}
$$

(12)

This algorithm is not very robust with nonstationarity input signal like speech signals. The first difficulty comes from $\alpha_{L,a} = \lambda \alpha_{L,a-1} \to 0$. This convergence to zero puts FTF algorithms and their numerically stable versions in very difficult situations. Instability may occur since we are trying to perform numerical divisions by very small values. To guard against this possibility, like it is often done with the NLMS algorithm, we append a small positive constant $c_a$ to the denominator

$$
\tilde{e}_{L,a} \to \frac{\tilde{e}_{L,a}}{\lambda \alpha_{L,a-1} + c_a}
$$

(13)

The second difficulty is that the forward predictor is locked over its last values. It is known that the FRLS algorithms were developed in the prewindowing case and all vectors are initialised by zero so that the algorithm starts adapting. In these conditions, when the input signal vanishes and reappears after a long period of time, the algorithm may diverge because of these nonzero values of the predictor. In other words, the algorithm is not well initialised when the signal reappears. In such conditions, it might be preferable to have the forward predictor $a_{L,a}$ return to zero by applying the following operation:

$$
a_{L,n} \to \eta a_{L,n}
$$

(14)

where $\eta$ is a constant close to one often called the leakage factor [12]. The likelihood variable is given by using the definition directly:

$$
\gamma_{L,n} = \frac{1}{1 + \lambda \tilde{e}_{L,a} x_{L,n}}
$$

(15)

Let us replace the quantity (*), that has not been used in $\tilde{k}_{L,a}$ of (12), by the variable $c_{L,a}$, we obtain:

$$
\begin{bmatrix}
k_{L,a} \\
c_{L,a}
\end{bmatrix} = \frac{-1}{\lambda \alpha_{L,a-1} + c_a} \begin{bmatrix}
\tilde{e}_{L,a} \\
\tilde{k}_{L,a-1}
\end{bmatrix} + \begin{bmatrix}
1 \\
-a_{L,a-1}
\end{bmatrix} \begin{bmatrix}
\tilde{e}_{L,a} \\
\tilde{k}_{L,a-1}
\end{bmatrix}
$$

(16)

We can write the input signal vector extended to the order $(L+1)$ in two different ways as shown below:

$$
\begin{bmatrix}
\mathbf{x}_{L+1,a} \\
\mathbf{x}_{L+1,n}
\end{bmatrix} = \begin{bmatrix}
\mathbf{x}_{L,n}^T, x_{n-L} \\
\mathbf{x}_{L,n}^T, x_{n-L}
\end{bmatrix}
$$

(17a)

$$
\begin{bmatrix}
\mathbf{x}_{L,n}^T \\
\mathbf{x}_{L,n}
\end{bmatrix} = \begin{bmatrix}
\mathbf{x}_{n}^T, \mathbf{x}_{n-L} \\
\mathbf{x}_{n}^T, \mathbf{x}_{n-L}
\end{bmatrix}
$$

(17b)

If we multiply on the left, the members of left and right of expression (16) by equations (17a) and (17b) respectively;

we get:

$$
\mathbf{x}^T_{L+1,a} \tilde{k} - c_{L,a} x_{n-L} = \mathbf{x}^T_{L+1,n} \tilde{k} - c_{L,a} x_{n-L} + \frac{\tilde{e}_{L,a}^2}{\lambda \alpha_{L,a-1} + c_a}
$$

(18)

By rearranging (18), we obtain a new recursive formula for calculating the likelihood variable which is much less

(Advance online publication: 19 August 2010)
complex than (15), the new expression is given below:

\[
\gamma_{L,n} = \frac{\gamma_{L,n-1}}{1 + \delta_{L,n} \gamma_{L,n-1}}
\]
\[
\delta_{L,n} = \frac{\sigma^2_{L,n}}{\lambda \alpha_{L,n-1} + c_u} - c_L n x_{n-L}
\]

The computational complexity of the M-SMFTF algorithm is 6L; as illustrated in Table II.

B. The RM-SMFTF Algorithm

The Reduced size predictors in the FTF algorithms have been successfully used in the FNTF algorithms [13]-[15]. The M-SMFTF algorithm can be easily used with reduced size prediction part. If we denote \( P \) the order of the predictor and \( L \) the size of adaptive filter, the forward predictor and the normalized Kalman gain are given respectively by:

\[
a_{L,n} = \begin{bmatrix} a_{P,n} \\ 0_{L-P} \end{bmatrix}
\]

\[
\begin{bmatrix} \bar{k}_{L,n} \\ c_{L,n} \end{bmatrix} = \begin{bmatrix} 0 \\ \bar{k}_{L,n-1} \end{bmatrix} + \frac{\sigma^2_{P,n}}{\lambda \alpha_{P,n-1} + c_u} \begin{bmatrix} -1 \\ 0_{L-P} \end{bmatrix} a_{P,n-1}
\]

where \( P \) is much smaller than \( L \). The first \((P+1)\) components of the \( \bar{k}_{L,n} \) are updated using the reduced size forward variables, the last components are just a shifted version of the \((P+1)\)th component of \( \bar{k}_{L,n} \). For this algorithm, we need two likelihood variables: the first one, \( \gamma_{P,n} \), is used to update the forward prediction error variance \( \alpha_{P,n} \), where \( c_{P,n} \) is \((P+1)\)th component of \( \bar{k}_{L,n} \). The second likelihood variable, \( \gamma_{L,n} \), is used to update the forward predictor \( a_{P,n} \) of order \( P \) and the transversal filter \( w_{L,n} \). The computational complexity of the reduced size M-SMFTF (RM-SMFTF) algorithm is \((2L+4P)\); it is given in Table III.

### C. Convergence analysis

The analysis uses the common independence assumption that the current input signal vector is statistically independent of the current coefficient vector of the adaptive filter. We define the weight-error vector at time \( n \) as:

\[
\Delta w_{L,n} = w_{\text{opt},L} - w_{L,n}
\]

The output a priori error \( \bar{e}_{L,n} \) can be written as:

\[
\bar{e}_{L,n} = v_n + x_n^T \Delta w_{L,n-1}
\]

The recursion in (3) on the coefficient error vector is:

\[
\Delta w_{L,n} = [I_L - \gamma_{L,n} \bar{k}_{L,n}^T x_{n,L}] \Delta w_{L,n-1} - \gamma_{L,n} \bar{k}_{L,n} v_n
\]

In a steady state operation, we can write:

\[
\alpha_{L,n-1} \rightarrow \alpha(\infty) = \gamma(\infty) \frac{\sigma^2_x}{1 - \lambda}
\]

where \( \gamma(\infty) \) is asymptotic value of the slowly variable \( \gamma_{L,n} \). The normalized Kalman gain becomes:

\[
\tilde{k}_{L,n} = \frac{1}{\lambda \alpha(\infty)} x_{L,n}
\]

Replacing the variable \( \gamma_{L,n} \) by its steady-state value \( \gamma(\infty) \) and using (26) and (27), the recursive expression (23) becomes:

\[
\Delta w_{L,n} = [I_L - (1-\lambda) \sigma^2_x x_{L,n} x_{L,n}^T] \Delta w_{L,n-1} - \frac{(1-\lambda)}{\lambda \sigma^2_x} v_n
\]
By taking the expected value of both sides of (28) and using the independence assumption to yield:

\[ E[\Delta w_{L,n}] = (2 - \lambda^{-1}) E[\Delta w_{L,n-1}] \]  

(29)

The steady-state solution of (29) is: If \( \lambda < 1 \) \( \Rightarrow \) \( E[\Delta w(x)] = 0 \) \( \lambda \); from which we obtain the steady-state mean coefficient vector of the M-SMFTF adaptive filter as:

\[ E[w(x)] = w_{opt,L} \]  

(30)

D. Analysis Prediction Part

We study the propagation of errors in all recursive quantities of the prediction part of the M-SMFTF algorithm. Assuming that the numerical errors are small, the model of error propagation in the recursive variables can be approximated by the following linear model:

\[ \Delta \phi_{n} = F(n) \Delta \phi_{n-1} + e(n) \]  

(31)

where \( e(n) \) represent the round-off noise. We can write the state vector of the errors at the time \( n \) as follows:

\[ \Delta \phi_{n} = \begin{bmatrix} \Delta \phi_{n-1}^T \\ \Delta \phi_{n-2}^T \end{bmatrix} \]  

(32)

where \( \Delta \phi_{n} = (\Delta a_{L,n}, \Delta \alpha_{L,n}, \Delta \gamma_{L,n}) \) and \( \Delta \phi_{n} = (\Delta \kappa_{L,n}, \Delta \gamma_{L,n}, \Delta \gamma_{L,n}) \) represent respectively the errors cumulated up until the time \( n \) in the forward and Kalman recursive variables. The \( (2L+2)\times(2L+2) \) dimensional matrix \( F(n) \) given by:

\[ F(n) = \begin{bmatrix} F_{11}(n) & F_{12}(n) \\ F_{21}(n) & F_{22}(n) \end{bmatrix} \]  

(33)

represents the transition matrix. The system (31) is said to be stable, in the mean sense, if the eigenvalues of \( E[F(n)] \), in the steady state, are all less than one in magnitude [9]. The operator \( E[\cdot] \) denotes the expected value. After a propagation analysis of the numerical errors of the 1st order and an asymptotic study of the equations of errors propagation, we approximate the errors in the forward variables ( \( \Delta a_{L,n}, \Delta \alpha_{L,n} \) ) and the Kalman variables ( \( \Delta \kappa_{L,n}, \Delta \gamma_{L,n} \) ) by the following linear first order models deduced from differentiating ( \( \Delta a_{L,n}, \alpha_{L,n} \) ) and ( \( \Delta \kappa_{L,n}, \gamma_{L,n} \) ) respectively:

\[ \Delta a_{L,n} = \eta[I_{L} - \gamma_{L,n-1}, \tilde{k}_{L,n-1}, \tilde{x}_{L,n}^{T}, p_{a}(n)] \Delta a_{L,n-1} + p_{a}(n) \]  

(34a)

\[ \Delta \alpha_{L,n} = \lambda \Delta \alpha_{L,n-1} + p_{a}(n) \]  

(34b)

\[ \Delta \kappa_{L,n} = M^{k} \Delta \kappa_{L,n-1} + p_{k}(n) \]  

(35a)

\[ \Delta \gamma_{L,n} = c^{T}(n) \Delta \gamma_{L,n-1} + p_{g}(n) \]  

(35b)

with

\[ M^{k} = \begin{bmatrix} 0_{L-1} & 0 \\ I_{L-1} & 0_{L-1} \end{bmatrix} \]  

(36)

\[ c^{T}(n) = \gamma_{L,n-1}^{T} (1 - \gamma_{L,n-1}) \]  

(37)

(38)

By assuming that the perturbation terms \( (p_{a}(n), p_{a}(n), p_{k}(n), p_{g}(n)) \) remain limited. In an asymptotic mode, we can write:

\[ \eta[I_{L} - \gamma_{L,n-1}, \tilde{k}_{L,n-1}, \tilde{x}_{L,n}^{T}, p_{a}(n)] \rightarrow \eta \lambda I_{L} \]  

(38)

\[ E[c^{T}(n)] \rightarrow \frac{1}{\lambda^{1} + \lambda^{-1}} \]  

(39)

We can thus say that the system is numerically stable, in the mean sense, for \( \lambda \) and \( \eta \) between zero and one.

We note that, the necessary condition of stability is the limit of the errors variance in the forward prediction. To calculate the covariance matrix of numerical errors in forward predictor; we use a statistical approach, 

\[ A_{n} = E[\Delta a_{L,n} \Delta a_{L,n}^{T}] \]  

We assume that the components of vector \( \Delta a_{L,n} \) independent between them and independent of the various theoretical variables given in the algorithm. With an input signal Gaussian sequence, we obtain the following expressions:

\[ A_{n} = G A_{n-1} + E[p_{a}(n)p_{a}^{T}(n)] \]  

(40)

\[ G = \eta^{2} (1 - 2(1 - \lambda) + (1 - \lambda)^{2}(L + 2)) \]  

(41)

The stability condition of equation (40) is given by the solution of the following inequality:

\[ |G| < 1 \]  

(42)

This inequality is only verified for this condition:

\[ 1 + \frac{1 + \frac{1}{(1 - \gamma_{L,n-1})^{2}}}{(L + 2)} \approx 1 - 1/L \]  

(43)

We note that the lower bound of this condition is always smaller than the lower bound of condition (10) of the original numerically stable FRLS algorithm. This means that we can choose smaller values for the forgetting factor for the proposed algorithm and consequently have faster convergence rate and better tracking ability.

IV. Simulation Results

To confirm the validity of our analysis and demonstrate the improved numerical performance, some simulations are carried out. All plots show the mean squared modeling versus the number of iterations. For the purpose of smoothing the curves, error samples are averaged over 256 points.
A. Comparative performances for stationary signals

We used a stationary correlated noise with a spectrum equivalent to the average spectrum of speech, called USASI noise in the field of acoustic echo cancellation. This signal, with mean zero and variance equal to 0.32, sampled at 16 kHz is filtered by impulse response which represents a real impulse response measured in a car and truncated to 256 samples. We compare the convergence speed and tracking capacity of the proposed (M-SMFTF, RM-SMFTF) algorithms with NS-FRLS and NLMS algorithms.

The filter length is $L=256$, the NLMS ($\mu=1$) and the NS-FRLS ($\lambda=1/3L$) algorithms are tuned to obtain fastest convergence. The forgetting factor $\lambda$ and the leakage factor $\eta$ for the proposed algorithms are chosen according to (43), $\lambda=1-1/L$ of the M-SMFTF and $\lambda=1-1/P$ of the RM-SMFTF algorithms, where $P$ is the predictor order.

The nonstationarity of the system to be modelled is simulated by introducing a linear gain variation on the impulse response at the 56320th samples. We compare the convergence speed and tracking capability of the reduced size predictor algorithm even for $P<<L$. The convergence speed and tracking capability of the reduced size predictor algorithm can be adjusted by changing the choice of the parameters $\lambda, \eta$ and $c_a$.

B. Comparative performances for speech signals

The input signal used in the simulations is speech signal, sampled at 16 kHz. We compare the convergence speed of the proposed algorithms with NS-FRLS and NLMS algorithms. We simulated an abrupt change in the impulse response at the 56320th samples. The choice of the forgetting factor for NS-FRLS algorithm to ensure numerical stability is $\lambda=1-1/10L$. The forgetting factor for M-SMFTF algorithm is $\lambda=1-1/L$ and for the RM-SMFTF algorithm the forgetting factor is $\lambda=1-1/P$, but the leakage $\eta$ and the constant $c_a$ must be carefully chosen.

In Fig.3, we can see that the initial convergence is almost the same for both M-SMFTF and NS-FRLS algorithms. However the proposed algorithm achieves better re-convergence after the abrupt change in the impulse response.

Different simulations have been done for different sizes $L$ and $P$, and all these results show that there is no degradation in the final steady-state $MSE(n)$ of the reduced size predictor algorithm even when $P<<L$. The convergence speed and tracking capability of the reduced size predictor algorithm can be adjusted by changing the choice of the parameters $\lambda, \eta$ and $c_a$.

V. CONCLUSION

We have presented a new algorithm M-SMFTF for adaptive filtering with fast convergence and low complexity. We have proposed more complexity reduction of simplified FTF type algorithm by using a new recursive method to compute the likelihood variable. The computational complexity of the M-SMFTF algorithm is $6L$ operations per sample and this computational complexity can be significantly reduced to $(2L+4P)$ when used with a reduced $P$-size $(P<<L)$ forward predictor. This can be very interesting for long filters. The low computational complexity of the M-SMFTF when dealing with long filters and its performance capabilities makes it very interesting for applications such as acoustic echo cancellation. The simulation has shown that the performances of the proposed algorithm are better than those of the normalized least mean square algorithm.
